Abstract. Researchers have used distributed constraint optimization problems (DCOPs) to model various multi-agent coordination and resource allocation problems. Very recently, Ottens et al. proposed a promising new approach to solve DCOPs that is based on confidence bounds via their Distributed UCT (DUCT) sampling-based algorithm. Unfortunately, its memory requirement per agent is exponential in the number of agents in the problem, which prohibits it from scaling up to large problems. Thus, in this paper, we introduce a new sampling-based DCOP algorithm called Distributed Gibbs, whose memory requirements per agent is linear in the number of agents in the problem. Additionally, we show empirically that our algorithm is able to find solutions that are better than DUCT; and computationally, our algorithm runs faster than DUCT as well as solve some large problems that DUCT failed to solve due to memory limitations.

1 Introduction

Distributed constraint optimization problems (DCOPs) are problems where agents need to coordinate their value assignments to maximize the sum of resulting constraint rewards [18, 21, 30]. Researchers have used them to model various multi-agent coordination and resource allocation problems such as the distributed scheduling of meetings [32], the distributed allocation of targets to sensors in a network [5, 33], the distributed allocation of resources in disaster evacuation scenarios [13], the distributed management of power distribution networks [12], the distributed generation of coalition structures [25] and the distributed coordination of logistics operations [14].

The field has matured considerably over the past decade as researchers continue to develop better and better algorithms. Most of these algorithms fall into

* A version of this paper appeared in AAMAS 2013 [19].
one of the following two classes of algorithms: (1) search-based algorithms like ADOPT [18] and its variants [29, 8], AFB [7] and MGM [16], where the agents enumerate through combinations of value assignments in a decentralized manner, and (2) inference-based algorithms like DPOP [21], max-sum [5] and Action GDL [26], where the agents use dynamic programming to propagate aggregated information to other agents.

More recently, Ottens et al. proposed a promising new approach to solve DCOPs that is based on confidence bounds [20]. They introduced a new sampling-based algorithm called Distributed UCT, which is an extension of UCB [1] and UCT [10]. While the algorithm is shown to outperform competing approximate and complete algorithms, its memory requirements per agent is exponential in the number of agents in the problem, which prohibits it from scaling up to large problems.

Thus, in this paper, we introduce a new sampling-based DCOP algorithm called Distributed Gibbs (D-Gibbs), which is a distributed extension of the Gibbs algorithm [6]. D-Gibbs is memory-bounded – its memory requirement per agent is linear in the number of agents in the problem. While the Gibbs algorithm was designed to approximate joint probability distributions in Markov random fields and solve maximum a posteriori (MAP) problems, we show how one can map such problems into DCOPs in order for Gibbs to operate directly on DCOPs. Our results show that D-Gibbs is able to find solutions that are better than DUCT faster than DUCT as well as solve some larger problems that DUCT failed to solve due to memory limitations.

2 Background: DCOP

A distributed constraint optimization problem (DCOP) [18, 17, 21] is defined by \( \langle X, D, F, A, \alpha \rangle \), where \( X = \{x_1, \ldots, x_n\} \) is a set of variables; \( D = \{D_1, \ldots, D_n\} \) is a set of finite domains, where \( D_i \) is the domain of variable \( x_i \); \( F \) is a set of binary utility functions, where each utility function \( F_{ij} : D_i \times D_j \rightarrow \mathbb{N} \cup \{0, \infty\} \) specifies the utility of each combination of values of variables \( x_i \) and \( x_j \); \( A = \{a_1, \ldots, a_p\} \) is a set of agents and \( \alpha : X \rightarrow A \) maps each variable to one agent. Although the general DCOP definition allows one agent to own multiple variables as well as the existence of n-ary constraints, we restrict our definition here for simplification purposes. One can transform a general DCOP to our DCOP using pre-processing techniques [31, 4, 2]. A solution is a value assignment for a subset of variables. Its utility is the evaluation of all utility functions on that solution. A solution is complete iff it is a value assignment for all variables. The goal is to find a utility-maximal complete solution.

A constraint graph visualizes a DCOP instance, where nodes in the graph correspond to variables in the DCOP and edges connect pairs of variables appearing in the same utility function. A DFS pseudo-tree arrangement has the same nodes and edges as the constraint graph and satisfies that (i) there is a subset of edges, called tree edges, that form a rooted tree and (ii) two variables in a utility function appear in the same branch of that tree. A DFS pseudo-tree

  \FOR {$i = 1$ \textbf{to} $n$}
    \STATE $z_i^t \leftarrow \text{SAMPLE}(P(z_i \mid z_1^t, \ldots, z_{i-1}^t, z_{i+1}^t, \ldots, z_n^{t-1}))$
  \ENDFOR
\ENDFOR
\end{algorithmic}

3 Background: Algorithms

We now provide a brief overview of two relevant sampling-based algorithms – the centralized Gibbs algorithm and the Distributed UCT (DUCT) algorithm.

3.1 Gibbs

The Gibbs sampling algorithm [6] is a Markov chain Monte Carlo algorithm that can be used to approximate joint probability distributions. It generates a Markov chain of samples, each of which is correlated with previous samples. Suppose we have a joint probability distribution $P(z_1, z_2, \ldots, z_n)$ over $n$ variables, which we would like to approximate. Algorithm 1 shows the pseudocode of the Gibbs algorithm, where each variable $z_i^t$ represents the $t$-th sample of variable $z_i$.

The algorithm first initializes $z_i^0$ to any arbitrary value of variable $z_i$ (lines 1-3). Then, it iteratively samples $z_i^t$ from the conditional probability distribution assuming that all the other $n-1$ variables take on their previously sampled values, respectively (lines 4-8). This process continues for a fixed number of iterations or until convergence, that is, the joint probability distribution approximated by the samples do not change. It is also common practice to ignore a number of samples at the beginning as it may not accurately represent the desired distribution. Once the joint probability distribution is found, one can easily identify that a complete solution with the maximum likelihood. This problem is called the maximum a posteriori (MAP) estimation problem, which is a common problem in applications such as image processing [3] and bioinformatics [28, 22].

The Gibbs sampling algorithm is desirable as its approximated joint probability distribution (formed using its samples) will converge to the true joint probability distribution given a sufficiently large number of samples for most problems. While Gibbs cannot be used to solve DCOPs directly, we will later show how one can slightly modify the problem such that Gibbs can be used to find optimal solutions given a sufficiently large number of samples.
3.2 Distributed UCT

The Upper Confidence Bound (UCB) [1] and UCB Applied to Trees (UCT) [10] algorithms are two Monte Carlo algorithms that have been successfully applied to find near optimal policies in large Markov Decision Processes (MDPs). The Distributed UCT (DUCT) algorithm [20] is a distributed version of UCT that can be used to find near-optimal cost-minimal complete DCOP solutions. We now provide a brief introduction to the algorithm and refer readers to the original article [20] for a more detailed treatment.

DUCT first constructs a pseudo-tree, after which each agent knows its parent, pseudo-parents, children and pseudo-children. Each agent $x_i$ maintains the following for all possible contexts $X$ and values $d \in D_i$:

- Its current value $d_i$.
- Its current context $X_i$, which is initialized to null. It is its assumption on the current values of its ancestors.
- Its cost $y_i$, which is initialized to $\infty$. It is the sum of the costs of all cost functions between itself and its ancestors given that they take on their respective values in its context and it takes on its current value.
- Its counter $\tau_i(X,d)$, which is initialized to 0. It is the number of times it has sampled value $d$ under context $X$.
- Its counter $\tau_i(X)$, which is initialized to 0. It is the number of times it has received context $X$ from its parent.
- Its cost $\hat{\mu}_i(X,d)$, which is initialized to $\infty$. It is the smallest cost found when it sampled $d$ under context $X$ so far up to the current iteration.
- Its cost $\hat{\mu}_i(X)$, which is initialized to $\infty$. It is the smallest cost found under context $X$ so far up to the current iteration.

At the start, the root agent chooses its value and sends it down in a CONTEXT message to each of its children. When an agent receives a CONTEXT message, it too chooses its value, appends it to the context in the CONTEXT message, and sends the appended context down in a CONTEXT message to each of its children. Each agent $x_i$ chooses its value $d_i$ using:

$$d_i = \arg\min_{d \in D_i} B_i(d)$$

(1)

$$B_i(d) = f(\delta_i(d), \hat{\mu}_i(X_i,d), \tau_i(X_i,d), B_c)$$

(2)

$$\delta_i(d) = \sum_{(x_j,d_j) \in X_i} F_{ij}(d,d_j)$$

(3)

where its bound $B_i(d)$ is initialized with a heuristic function $f$ that balances exploration and exploitation. Additionally, each agent $x_i$ increments the number of times it has chosen its current value $d_i$ under its current context $X_i$ using:

$$\tau_i(X_i,d_i) = \tau_i(X_i,d_i) + 1$$

(4)

$$\tau_i(X_i) = \tau_i(X_i) + 1$$

(5)
This process continues until leaf agents receive CONTEXT messages and choose their respective values. Then, each leaf agent calculates its cost and sends it up in a COST message to its parent. When an agent receives a COST message from each of its children, it too calculates its cost, which includes the costs received from its children, and sends it up to its parent. Each agent calculates its costs \( y_i, \hat{\mu}_i(X_i, d_i) \) and \( \hat{\mu}_i(X_i) \) using:

\[
y_i = \delta_i(d_i) + \sum_{x_c \in C_i} y_c
\] (6)

\[
\hat{\mu}_i(X_i, d_i) = \min\{\hat{\mu}_i(X_i, d_i), y_i\}
\] (7)

\[
\hat{\mu}_i(X_i) = \min\{\hat{\mu}_i(X_i), \hat{\mu}_i(X_i, d_i)\}
\] (8)

This process continues until the root agent receives a COST message from each of its children and calculates its own cost. Then, the root agent starts a new iteration, and the process continues until all the agents terminate. An agent \( x_i \) terminates if its parent has terminated and the following condition holds:

\[
\max_{d \in D_i} \left\{ \mu_i(X_i) - \left[ \hat{\mu}_i(X_i, d) - \sqrt{\ln \frac{2}{\Delta_i}} \right] \right\} \leq \epsilon
\] (9)

where \( \Delta \) and \( \epsilon \) are parameters of the algorithm.

4 Distributed Gibbs

While DUCT has been shown to be very promising, its memory requirement per agent is \( O(\hat{D}^T) \), where \( \hat{D} = \max_i D_i \) is the largest domain size over all agents and \( T \) is the depth of the pseudo-tree. Each agent needs to store a constant number of variables for all possible contexts and values, and the number of possible contexts is exponential in the number of ancestors. Therefore, this high memory requirement might prohibit the use of DUCT in large problems, especially if the agents have large domain sizes as well. Therefore, we now introduce the Distributed Gibbs algorithm, which is a distributed extension of the Gibbs algorithm adapted to solve DCOPs. Additionally, its memory requirement per agent is linear in the number of ancestors.

4.1 Mapping of MAP Estimation Problems to DCOPs

Recall that the Gibbs algorithm approximates a joint probability distribution over all the variables in a problem when only marginal distributions are available. Once the joint probability distribution is found, it finds the maximum a posteriori (MAP) solution. If we can map a DCOP where the goal is to find a complete solution with maximum utility, to a problem where the goal is to find a complete solution with the maximum likelihood, and that a solution with maximum utility is also a solution with maximum likelihood, then we can use Gibbs to solve DCOPs.
We now describe how to do so. Consider a maximum a posteriori (MAP) estimation problem on a pairwise Markov random field (MRF). An MRF can be visualized by an undirected graph $\langle V, E \rangle$ and is formally defined by

- A set of random variables $X = \{ x_i \mid \forall i \in V \}$, where each random variable $x_i$ can be assigned a value $d_i$ from a finite domain $D_i$. Each random variable $x_i$ is associated with node $i \in V$.
- A set of potential functions $\theta = \{ \theta_{ij}(x_i, x_j) \mid \forall (i, j) \in E \}$. Each potential function $\theta_{ij}(x_i, x_j)$ is associated with edge $(i, j) \in E$. Let the probability $P(x_i = d_i, x_j = d_j)$ be defined as $\exp(\theta_{ij}(x_i = d_i, x_j = d_j))$. For convenience, we will drop the values in the probabilities and use $P(x_i, x_j)$ to mean $P(x_i = d_i, x_j = d_j)$ from now on.

Therefore, a complete assignment $x$ to all the random variables has the probability:

$$P(x) = \frac{1}{Z} \prod_{(i, j) \in E} \exp[\theta_{ij}(x_i, x_j)] = \frac{1}{Z} \exp \left[ \sum_{(i, j) \in E} \theta_{ij}(x_i, x_j) \right] \quad (10)$$

where $Z$ is the normalization constant. The objective of a MAP estimation problem is to find the most probable assignment to all the variables under $P(x)$, which is equivalent to finding a complete assignment $x$ that maximizes the function:

$$F(x) = \sum_{(i, j) \in E} \theta_{ij}(x_i, x_j) \quad (11)$$

Maximizing the function in Equation 11 is also the objective of a DCOP if each potential function $\theta_{ij}$ corresponds to a utility function $F_{ij}$. Therefore, if we use the Gibbs algorithm to solve a MAP estimation problem, then the complete solution found for the MAP estimation problem is also a solution to the corresponding DCOP.

### 4.2 Algorithm Description

We now describe the Distributed Gibbs algorithm. Algorithm 2 shows the pseudo-code, where each agent $x_i$ maintains the following:

- Its values $d_i$ and $\hat{d}_i$, which are both initialized to initial value $\text{ValInit}(x_i)$. They are the agent’s value in the current and previous iterations, respectively.
- Its best value $d^*_i$, which is also initialized to initial value $\text{ValInit}(x_i)$. It is the agent’s value in the best solution found so far. Note that each agent maintains its own best value only and does not need to know the best values of other agents. The best solution $x^* = (d^*_1, ..., d^*_n)$ can then be constructed upon termination.
- Its current context $X_i$, which is initialized with all the tuples of neighbors and their initial values. It is its assumption on the current values of its neighbors.

---

1 We are describing pairwise MRFs so that the mapping to binary DCOPs is clearer.
Algorithm 2: Distributed Gibbs()

1. Create pseudo-tree
2. Each agent $x_i$ calls Initialize()

Procedure Initialize()

3. $d^*_i \leftarrow \hat{d}_i \leftarrow d_i \leftarrow \text{ValInit}(x_i)$
4. $X_i \leftarrow \{(x_j, \text{ValInit}(x_j)) \mid x_j \in N_i\}$
5. $\Delta^*_i \leftarrow \Delta_i \leftarrow 0$
6. $t^*_i \leftarrow t_i \leftarrow 0$
7. if $x_i$ is root then
   8.      $t_i \leftarrow t_i + 1$
9.      SAMPLE()
10. end

- Its time index $t_i$, which is initialized to 0. It is the number of iterations it has sampled.
- Its time index $t^*_i$, which is initialized to 0. It indicates the most recent iteration that a better solution was found. The agents use it to know if they should update their respective best values.
- Its value $\Delta_i$, which is initialized to 0. It is the difference in solution quality between the current solution and the best solution found in the previous iteration.
- Its value $\Delta^*_i$, which is initialized to 0. It is the difference in solution quality between the best solution found in the current iteration and the best solution found so far up to the previous iteration.

The algorithm starts by constructing a pseudo-tree (line 1) and having each agent initialize their variables to their default values (lines 2-6). The root then starts by sampling, that is, choosing its value $d_i$ based on the probability:

$$P(x_i \mid x_j \in \mathcal{X} \setminus \{x_i\}) = P(x_i \mid x_j \in N_i)$$

$$= \frac{1}{Z} \prod_{(x_j, d_j) \in X_i} \exp[F_{ij}(d_i, d_j)]$$

$$= \frac{1}{Z} \exp\left[\sum_{(x_j, d_j) \in X_i} F_{ij}(d_i, d_j)\right]$$

(12)

where $Z$ is the normalization constant (lines 9 and 12). It then sends its value in a VALUE message to each of its neighbors (line 19).

When an agent receives a VALUE message, it updates the value of the sender in its context (line 20). If the message is from its parent, then it too samples and sends its value in a VALUE message to each of its neighbors (lines 32, 12 and 19). This process continues until all the leaf agents sample. Each leaf agent then sends a BACKTRACK message to its parent (line 34). When an agent receives a BACKTRACK message from each child (line 38), it too sends a BACK-

29 \Delta_i \leftarrow \Delta_s \\
30 \Delta^*_i \leftarrow \Delta^*_s \\
31 \quad t^*_i \leftarrow t^*_s \\
32 \text{SAMPLE()} \\
33 \text{if } x_i \text{ is a leaf then} \\
34 \quad \text{Send BACKTRACK } (x_i, \Delta_i, \Delta^*_i) \text{ to } P_i \\
35 \text{end} \\
36 \text{end}

We now describe how the agents identify if they have found a better solution than the best one found thus far in a decentralized manner without having to know the values of every other agent in the problem. In order to do so, the agents use delta variables $\Delta_i$ and $\Delta^*_i$. These variables are sent down the pseudo-tree in VALUE messages together with the current value of agents (line 19) and up the pseudo-tree in BACKTRACK messages (lines 34 and 46). When an agent receives a VALUE message from its parent, it updates its delta values to its parents' delta values prior to sampling (lines 29-30). After sampling, each agent calculates its local difference in solution quality $\sum_{(x_j,d_j) \in X_i} [F_{ij}(d_i,d_j) - \hat{F}_{ij}(\hat{d}_i,d_j)]$ and adds it to $\Delta_i$ (line 13). Thus, $\Delta_i$ can be seen as a sum of local differences from the root to the current agent as it is updated down the pseudo-tree. If this difference $\Delta_i$ is larger than the maximum difference $\Delta^*_i$, which means
When Received BACKTRACK($x_s, \Delta_s, \Delta^*_s$)

37 Store $\Delta_s$ and $\Delta^*_s$
38 if Received BACKTRACK message from all children in this iteration then
39     $\Delta_i \leftarrow (\sum_{x_c \in C_i} \Delta_c) - (|C_i| - 1) \cdot \Delta_i$
40     $\Delta^*_C_i \leftarrow (\sum_{x_c \in C_i} \Delta^*_c) - (|C_i| - 1) \cdot \Delta^*_i$
41     if $\Delta^*_C_i > \Delta^*_i$ then
42         $\Delta^*_i \leftarrow \Delta^*_C_i$
43         $d_i^* \leftarrow d_i$
44         $t_i^* \leftarrow t_i$
45     end
46     Send BACKTRACK ($x_i, \Delta_i, \Delta^*_i$) to $P_i$
47     if $x_i$ is root then
48         $\Delta_i \leftarrow \Delta_i - \Delta^*_i$
49         $\Delta^*_i \leftarrow 0$
50         $t_i \leftarrow t_i + 1$
51         SAMPLE()
52     end
53 end

that the new solution is better than the best solution found thus far, then the agent updates the maximum difference $\Delta^*_i$ to $\Delta_i$ and its best value $d_i^*$ to its current value $d_i$ (lines 14-16).

After finding a better solution, the agent needs to inform other agents to update their respective best values to their current values since the best solution found thus far assumes that the other agents take on their respective current values. There are the following three types of agents that need to be informed:

- **Descendant agents:** The agent that has found a better solution updates its time index $t_i^*$ to the current iteration (line 17) and sends this variable down to its children via VALUE messages (line 19). If an agent $x_i$ receives a VALUE message from its parent with a time index $t_s^*$ that equals the current iteration $t_i$, then it updates its best value $d_i^*$ to its current value $d_i$ (lines 24-25). It then updates its time index $t_i^*$ to its parent’s time index $t_s^*$ and sends it down to its children via VALUE messages (lines 31, 32 and 19). This process continues until all descendant agents update their best values.

- **Ancestor agents:** The agent that has found a better solution sends its maximum difference $\Delta^*_i$ up to its parent via BACKTRACK messages (lines 34 and 46). In the simplest case where an agent $x_i$ has only one child $x_c$, if the agent receives a BACKTRACK message with a maximum difference $\Delta^*_c$ larger than its own maximum difference, then it updates its best value $d_i^*$ to its current value $d_i$ (lines 40, 41 and 43). In the case where an agent has more than one child, then it compares the sum of the maximum differences over all children $x_c$ subtracted by the overlaps ($\Delta^*_i$ was added an extra $|C_i|$ times) with its own maximum difference $\Delta^*_i$. If the former is larger than the latter, then it updates its best value $d_i^*$ to its current value $d_i$ (lines 40, 41 and 43). It then updates its own maximum difference $\Delta^*_i$ (line 42) and sends it to its
parent via BACKTRACK messages (line 46). This process continues until all ancestor agents update their best values.

- **Sibling subtree agents:** Agents in sibling subtrees do not get VALUE or BACKTRACK messages from each other. Thus, an agent \( x_i \) cannot update its best value using the above two methods if another agent in its sibling subtree has found a better solution. However, in the next iteration, the common ancestor of these two agents will propagate its time index down to agent \( x_i \) via VALUE messages. If agent \( x_i \) receives a time index \( t^*_i \) that equals the previous iteration \( t_i - 1 \) and is larger than its own time index \( t^*_i \) (indicating that it hasn’t found an even better solution in the current iteration), then it updates its best value \( d^*_i \) to its previous value \( \hat{d}_i \) (lines 26-28). (It doesn’t update its best value to its current value because the best solution was found in the previous iteration.) Thus, all agents in sibling subtrees also update their best values.

Therefore, when a better solution is found, all agents in the Distributed Gibbs algorithm update their best values by the end of the next iteration. The algorithm can either terminate after a given number of iterations or when no better solution is found for a given number of consecutive iterations. We later show that by choosing at least \( \frac{1}{\alpha \epsilon} \) number of samples, the probability that the best solution found is in the top \( \alpha \)-percentile is at least \( 1 - \epsilon \) (Theorem 2).\(^2\)

### 4.3 Theoretical Properties

Like Gibbs, the Distributed Gibbs algorithm also samples the values sequentially and samples based on the same equation (Equation 12). The main difference is that Gibbs samples down a pseudo-chain (a pseudo-tree without sibling subtrees), while Distributed Gibbs exploits parallelism by sampling down a pseudo-tree. However, this difference only speeds up the sampling process and does not affect the correctness of the algorithm since agents in sibling subtrees are independent of each other. Thus, we will show several properties that hold for centralized Gibbs and, thus, also hold for Distributed Gibbs. Some of these properties are well-known (we label them “properties”) and some are new properties (we label them “theorems”) to the best of our knowledge. The proofs for the new properties are available in [19].

**Property 1.** Gibbs is guaranteed to converge.

**Property 2.** Upon convergence, the probability \( P(\mathbf{x}) \) of any solution \( \mathbf{x} \) equals its approximated probability \( P_{\text{Gibbs}}(\mathbf{x}) \):

\(^2\) One can slightly optimize the algorithm by having the agents (1) send their current values in BACKTRACK messages instead of VALUE messages to their parents; and (2) send smaller VALUE messages, which do not contain delta values and time indices, to all pseudo-children. We describe the unoptimized version here for ease of understanding.
\[ P(x) = P_{\text{Gibbs}}(x) = \frac{\exp[F(x)]}{\sum_{x' \in S} \exp[F(x')]} \]

where \( S \) is the set of all solutions sampled.

**Property 3.** The expected numbers of samples \( N_{\text{Gibbs}} \) to get optimal solution \( x^* \) is

\[ E(N_{\text{Gibbs}}) \leq \frac{1}{P_{\text{Gibbs}}(x^*)} + L \]

where \( L \) is the number of samples needed before the estimated joint probability converges to the true joint probability.

The process of repeated sampling to get an optimal solution is equivalent to sampling Bernoulli trials with success probability \( P_{\text{Gibbs}}(x^*) \). Thus, the corresponding geometric variable for the number of samples needed to get an optimal solution for the first time has an expectation of \( 1/P_{\text{Gibbs}}(x^*) \) \([11]\). In the following, we assume that \( 1/P_{\text{Gibbs}}(x^*) >> L \) and we will thus ignore \( L \).

**Theorem 1.** The expected number of samples to find an optimal solution \( x^* \) with Gibbs is no greater than with a uniform sampling algorithm. In other words,

\[ P_{\text{Gibbs}}(x^*) \geq P_{\text{uniform}}(x^*) \]

**Definition 1** A set of top \( \alpha \)-percentile solutions \( S_\alpha \) is a set that contains solutions that are no worse than any solution in the supplementary set \( D \setminus S \) and \( |S_\alpha|/|D| = \alpha \).

**Theorem 2.** After \( N = \frac{1}{\alpha \epsilon} \) number of samples with Gibbs, the probability that the best solution found thus far \( x_N \) is in the top \( \alpha \)-percentile is at least \( 1 - \epsilon \). In other words,

\[ P_{\text{Gibbs}} \left( x_N \in S_\alpha \mid N = \frac{1}{\alpha \epsilon} \right) \geq 1 - \epsilon \]

**Corollary 1.** The quality of the solution found by Gibbs approaches optimal as the number of samples \( N \) approaches infinity. In other words,

\[ \lim_{\epsilon \to 0} P_{\text{Gibbs}} \left( x_N \in S_\alpha \mid N = \frac{1}{\alpha \epsilon} \right) = 1 \]

While we have only described the above properties and theorems for problems with discrete values, we believe that they can be applied directly for DCOPs with continuous values \([23]\) by changing the summations to integrations.
4.4 Complexity Analysis

Each agent $x_i$ needs to store a context $X_i$, which contains the agent-value pairs of all neighboring agents $x_j \in N_i$. Additionally, agent $x_i$ needs to store the delta values $\Delta_c$ and $\Delta^*_c$ for all children $x_c \in C_i$. Thus, the memory complexity of each agent is linear in the number of agents in the problem ($= O(|X|)$).

Each agent $x_i$ needs to send a VALUE message to each neighboring agent and a BACKTRACK message to its parent in each iteration, and each message contains a constant number of values (each VALUE message contains 5 values and each BACKTRACK message contains 3 values). Thus, the amount of information passed around in the network per iteration is polynomial in the number of agents in the problem ($= O(|X|^2)$).

5 Experimental Results

We now compare Distributed Gibbs (D-Gibbs) to DPOP [21] (an optimal algorithm) and MGM [16], MGM2 [16] and DUCT [20] (sub-optimal algorithms). In terms of network load, that is, the amount of information passed around the network, DPOP sends an exponential amount of information in total ($= O(\exp(|X|))$) while MGM, MGM2, DUCT and D-Gibbs send a polynomial amount of information in each iteration ($= O(|X|^2)$).

To compare runtimes and solution qualities, we use publicly-available implementations of MGM, MGM2, DUCT and DPOP, which are all implemented on

Fig. 1. Results for Graph Coloring Problems
the FRODO framework [15]. We run our experiments on a 64 core Linux machine with 2GB of memory per run. We measure runtime using the simulated time metric [24] and evaluate the algorithms on graph coloring problems. For all problems, we set the DUCT parameters $\Delta = \epsilon = 0.05$, similar to the settings used in the original article [20] unless mentioned otherwise. We also let MGM, MGM2 and D-Gibbs run for as long as DUCT did for fair comparisons. Each data point is averaged over 50 instances.

We used the random graph coloring problem generator provided in the FRODO framework [15] to generate our problems. We varied the size of the problem by increasing the number of agents $|X|$ from 18 to 30, the graph density $p_1$ from 0.2 to 1.0 and the domain size $|D_i|$ of each agent $x_i$ from 5 to 20, and we chose the constraint utilities uniformly from the range $(0, 10)$ at random if the neighboring agents have different values and 0 if they have the same value. Figure 1 shows our results, where we varied the number of agents $|X|$ in Figure 1(a), the domain size $|D_i|$ in Figure 1(b), the density $p_1$ in Figure 1(c) and the DUCT parameters $\Delta$ and $\epsilon$ in Figure 1(d). DPOP ran out of memory for problems with 20 agents and above, and DUCT ran out of memory for problems with domain sizes 18 and 19 and for problems with a density of 1.

In all four figures, DPOP found better solutions (when it did not run out of memory) than D-Gibbs, which found better solutions than MGM, MGM2 and DUCT. The difference in solution quality increases as the number of agents, domain size and density increases.

Additionally, in Figure 1(d), as $\Delta$ and $\epsilon$ decreases, the runtimes of DUCT (and thus of all the other algorithms also since we let them run for as long as DUCT) increases since the tolerance for error decreases. However, the quality of its solutions improves as a result. Interestingly, the quality of solutions found by D-Gibbs, MGM and MGM2 remained relatively unchanged despite given more runtime, which means that they found their solutions very early on. Thus, D-Gibbs found close to optimal solutions faster (when $\Delta = \epsilon = 0.1$) than DUCT (when $\Delta = \epsilon = 0.01$).

6 Conclusions

Researchers have not investigated sampling-based approaches to solve DCOPs until very recently, where Ottens et al. introduced the Distributed UCT (DUCT) algorithm, which uses confidence-based bounds. However, one of its limitation is its memory requirement per agent, which is exponential in the number of agents in the problem. This large requirement prohibits it from scaling up to large problems. Examples include problems with domain sizes 19 and 20 or problems with a density of 1, which we showed experimentally. Therefore, in this paper, we introduce a new sampling-based algorithm called Distributed Gibbs (D-Gibbs),

---

3 Exceptions are when DUCT failed to find a solution due to insufficient memory. For domain size $|D_i| = 19$ and 20 in Figure 1(b), we let the other algorithms run for as long as DUCT did for domain size $|D_i| = 18$, and for density $p_1 = 1$ in Figure 1(c), we let the other algorithms run for as long as DUCT did for density $p_1 = 0.9$. 

---
whose memory requirement per agent is linear in the number of agents in the problem. It is a distributed extension of Gibbs, which was originally designed to approximate joint probability distributions in Markov random fields. We experimentally show that D-Gibbs finds better solutions compared to competing local search algorithms like MGM and MGM2 in addition to DUCT. Additionally, we also show how one can choose the number of samples based on the desired a priori approximation bound (using Theorem 2). While we have described D-Gibbs for (discrete-valued) DCOPs, we believe that it can easily be extended to solve continuous-valued DCOPs [23] as well. Thus, we would like to compare this approach with the Continuous-Valued Max-Sum [23, 27] in the future.
